

California reservoir network optimization with daily ensemble hydrologic forecasts

Jon Herman

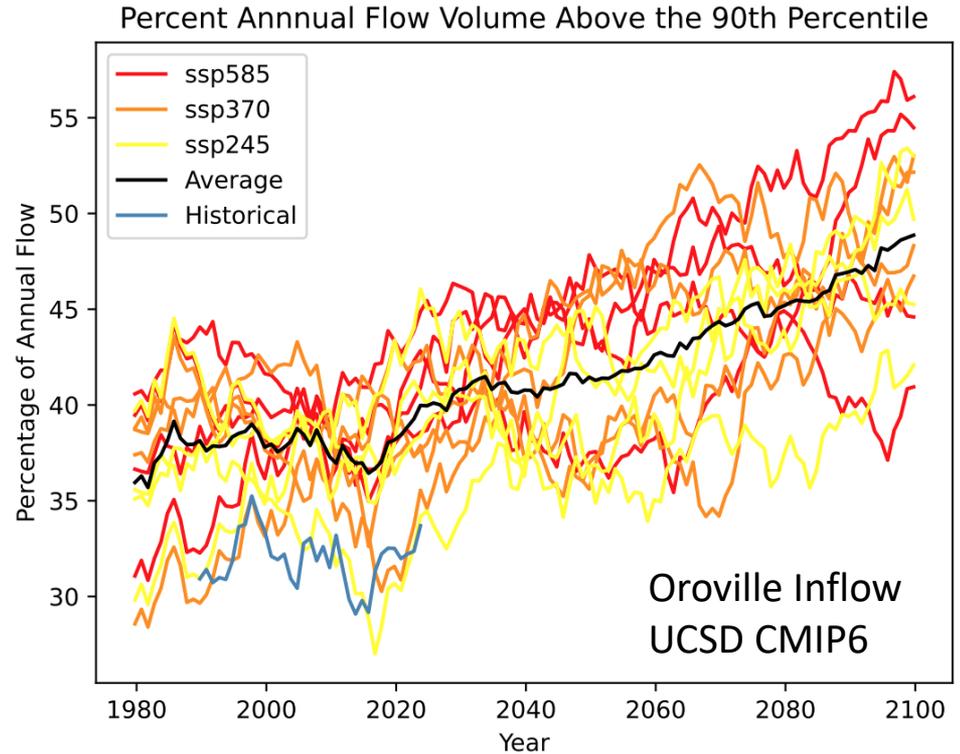

Associate Professor

UC Davis Civil & Environmental Engineering

CWEMF 2025

Daily models: Flood control = Water supply

- 30-50% of CA annual water supply from high-flow events
- Climate change impacts: more extreme precipitation, shift from snow to rain
- Opportunities for offstream storage and groundwater banking

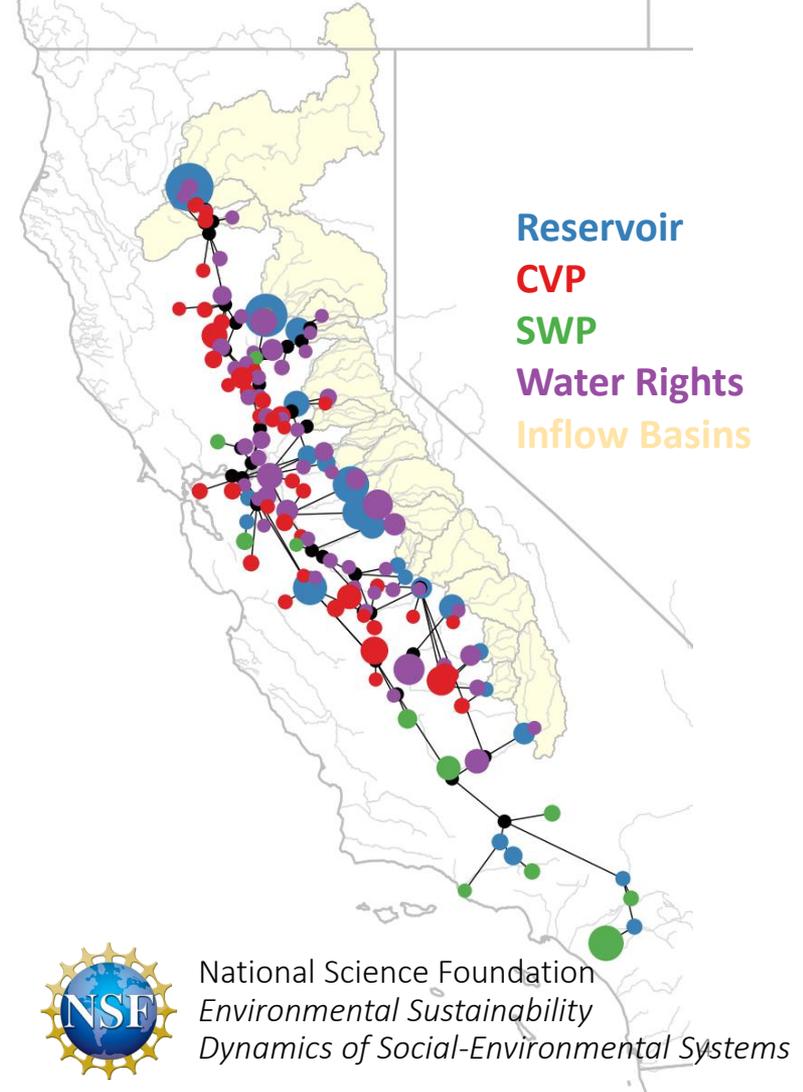

Goals for a model

- Time/space scale: statewide, daily
- Flood control and water supply operations
- Optimization to adapt to changing conditions
- Routing and conveyance constraints
- Decision making based on forecasts

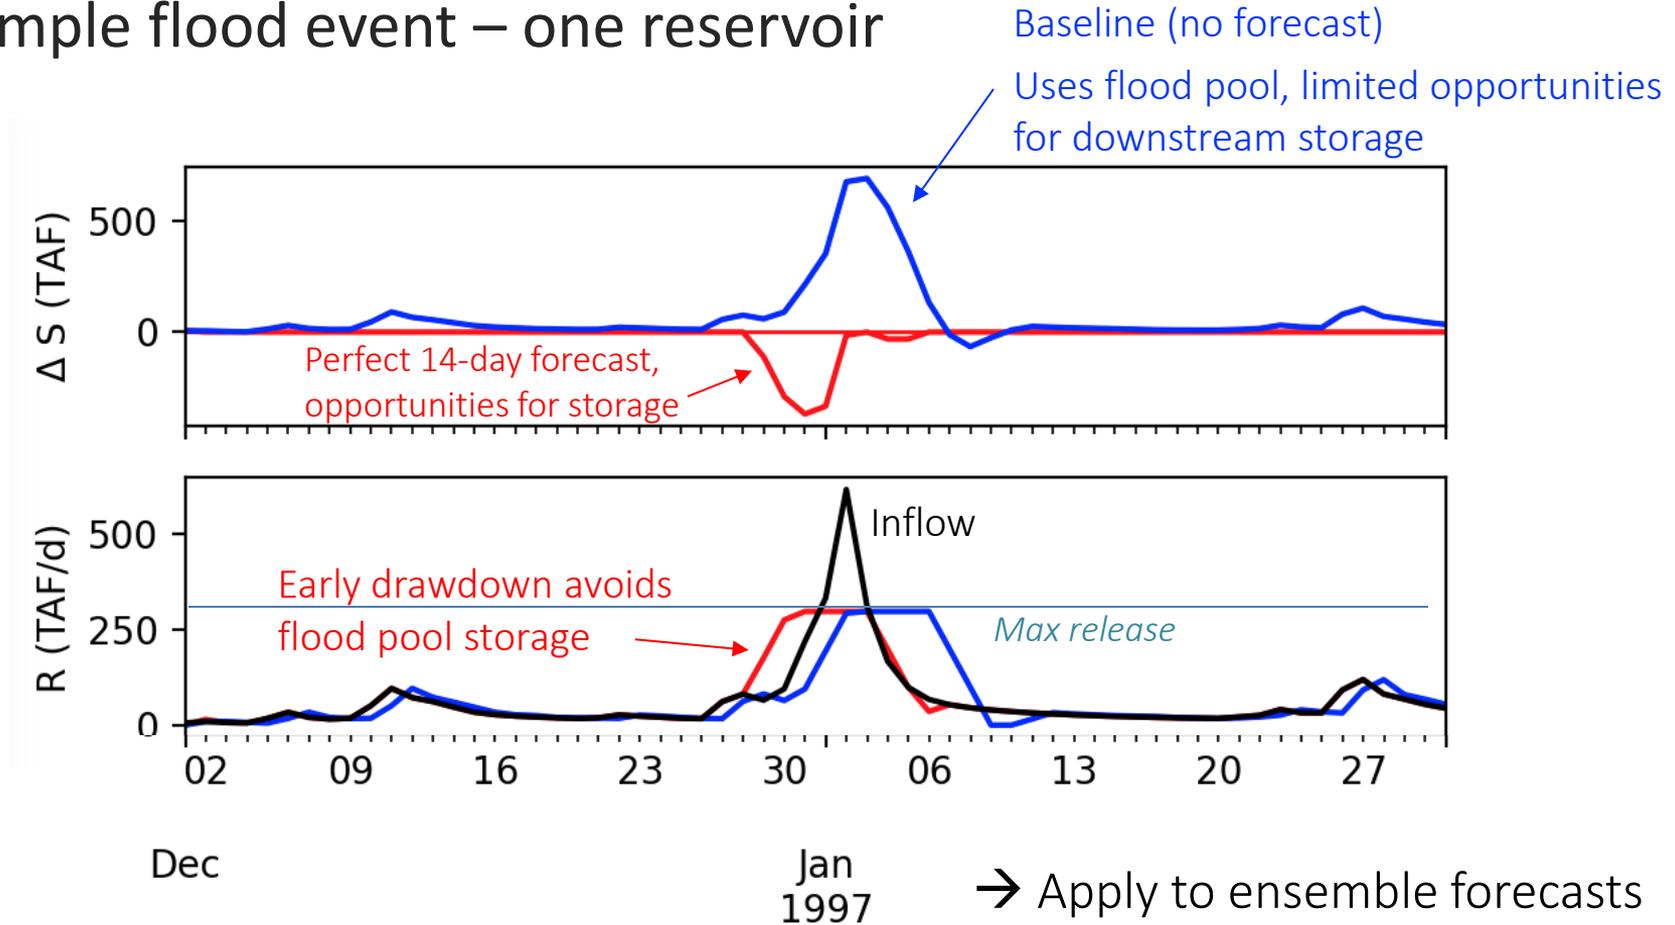

- Current models contain many of these, but not all

CA network optimization with model predictive control (MPC)

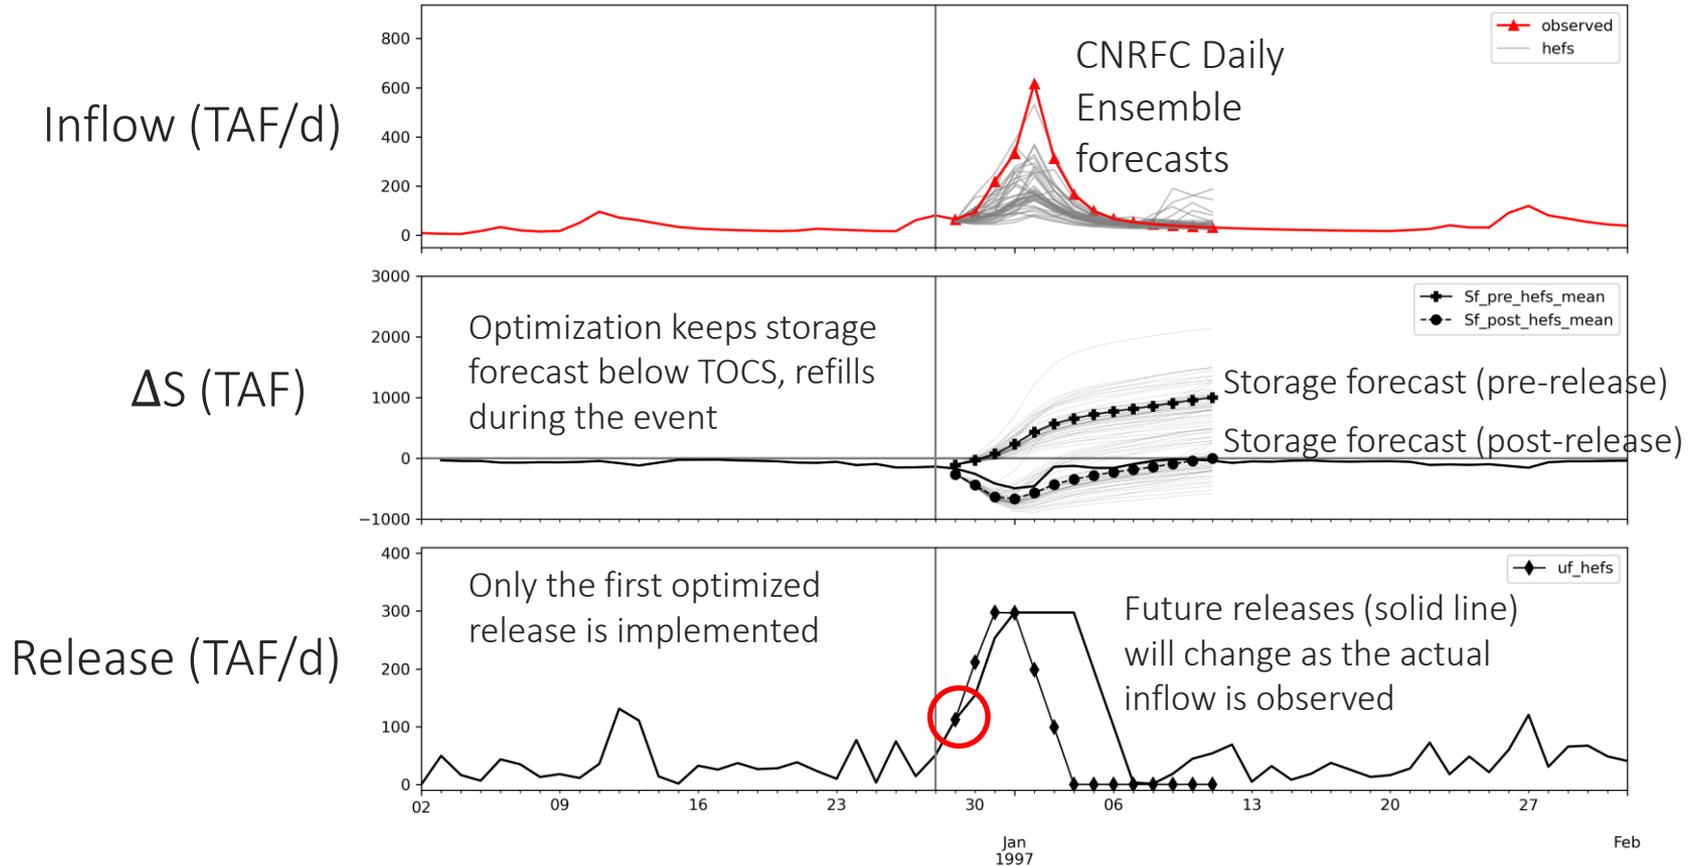

- CNRFC HEFS forecasts for inflow basins
- Network size ~200 nodes, 200 links
- All SW entitlements (CVP, SWP, Water Rights) from Sacramento-San Joaquin
- Muskingum routing
- Today: introduce model, data, and example results for 1997 flood

Example flood event – one reservoir

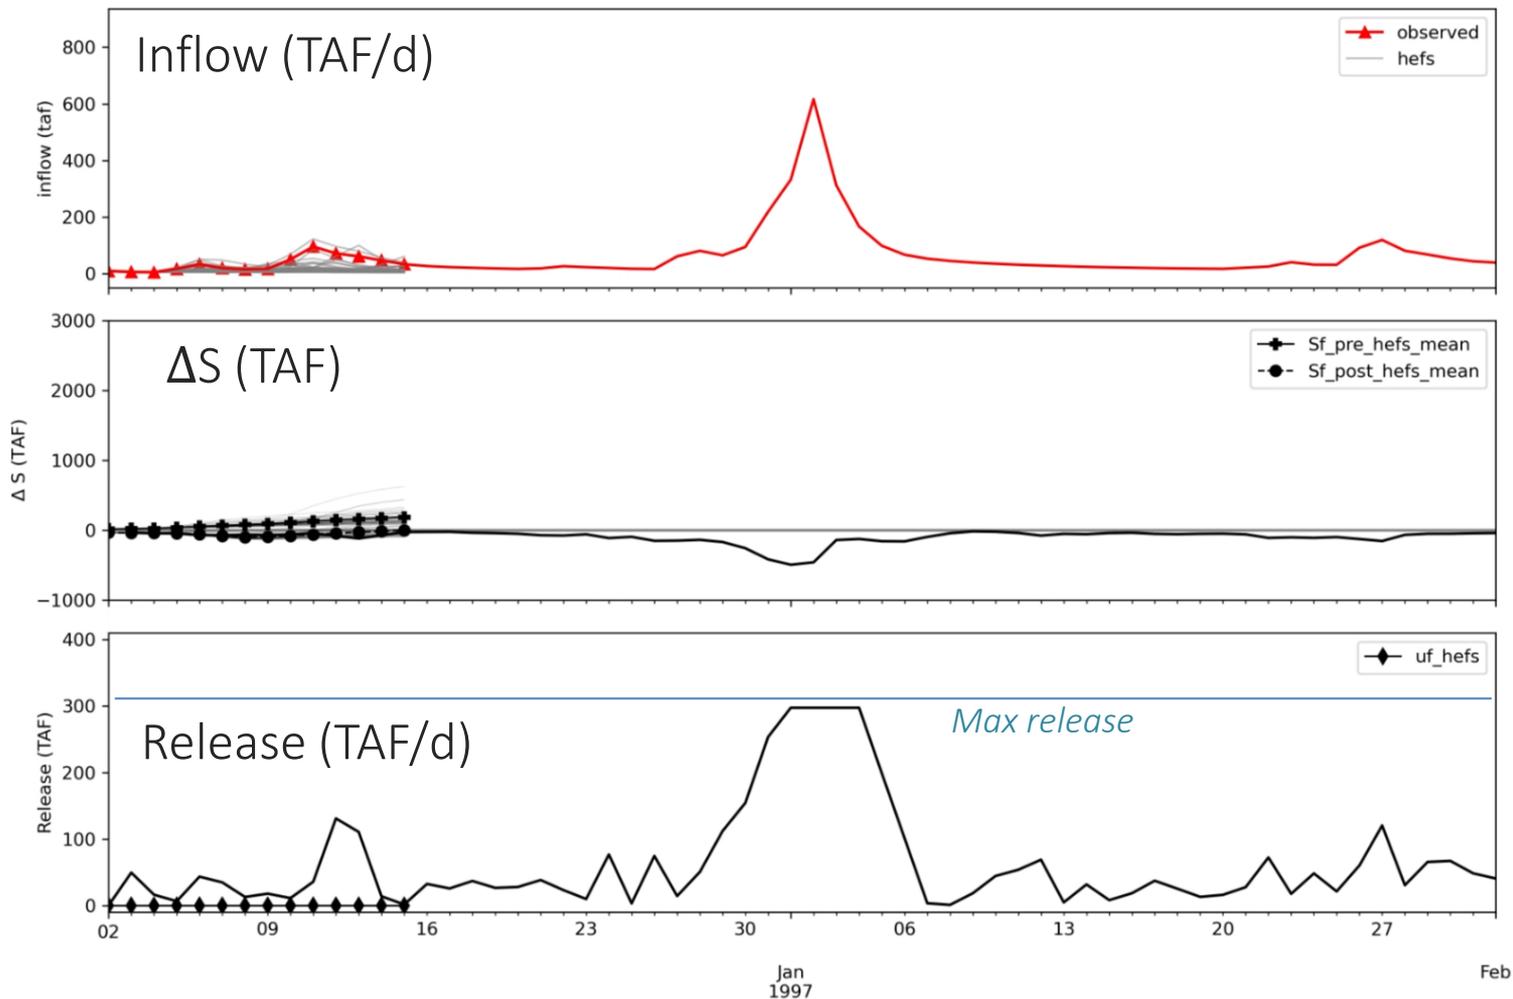

Model predictive control (MPC) – rolling horizon optimization

Animation

Example for Oroville 1997

(Alex Chen, UC Davis)

Data: Water infrastructure

Nodes: capacity, top of conservation (TOCS)

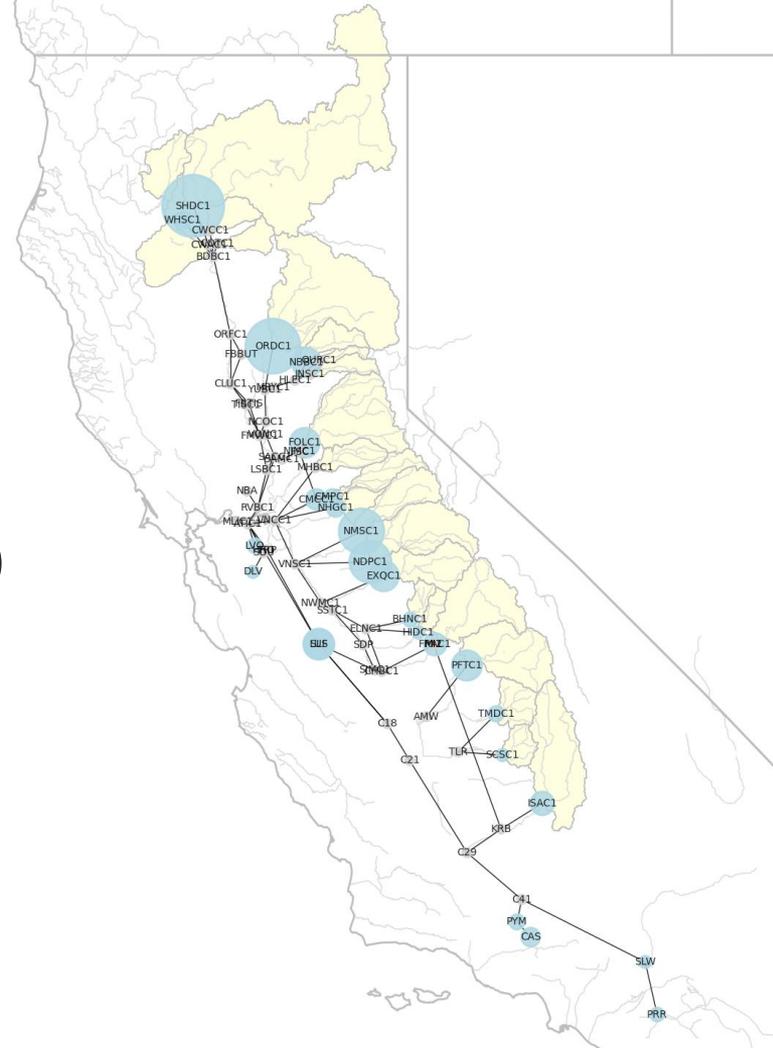

Links: maximum flow, Muskingum K,X

Observations: CNRFC/CDEC

Hindcasts: CNRFC HEFS (courtesy Brett Whitin)

- WY 1990-2023
- 365-day lead time, using 14 for now

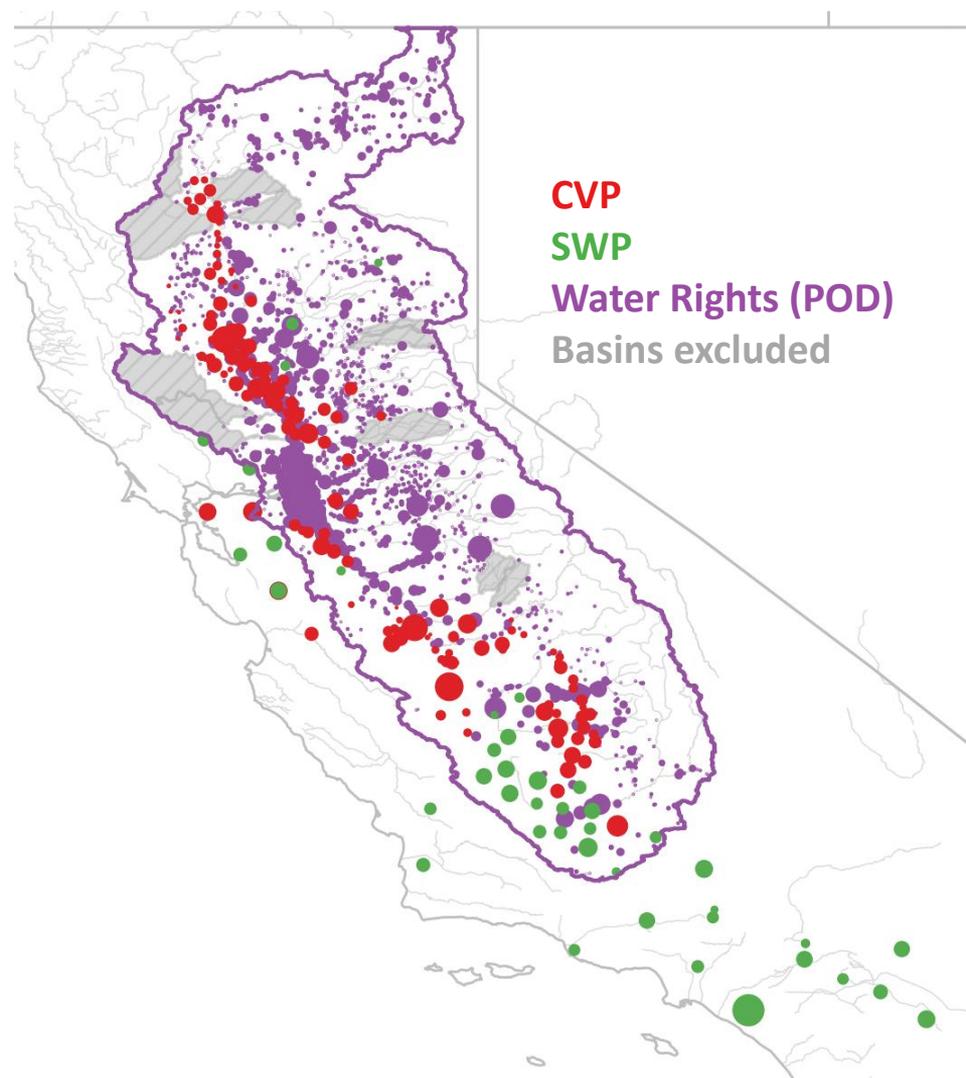

Connectivity, max flow, travel time
from DWR schematics
(Links in references)

Data: Surface water entitlements

Hagerty, N. (2022) *Adaptation to Surface Water Scarcity in Irrigated Agriculture*.

- SWP, CVP (13 contract types)
- Rights: average reported diversion
 - Filter rights with POD in Sac-SJ basin
- Demand nodes grouped by type and nearest infrastructure node
- >3000 entitlements → 112 nodes

Problem formulation: MPC at one timestep

Decision Variables: flow on each link for each timestep in forecast horizon (upstream, downstream, and emergency flows)

Parameters:

Inflow forecasts, connectivity matrices, initial storage, top of conservation

Constraints:

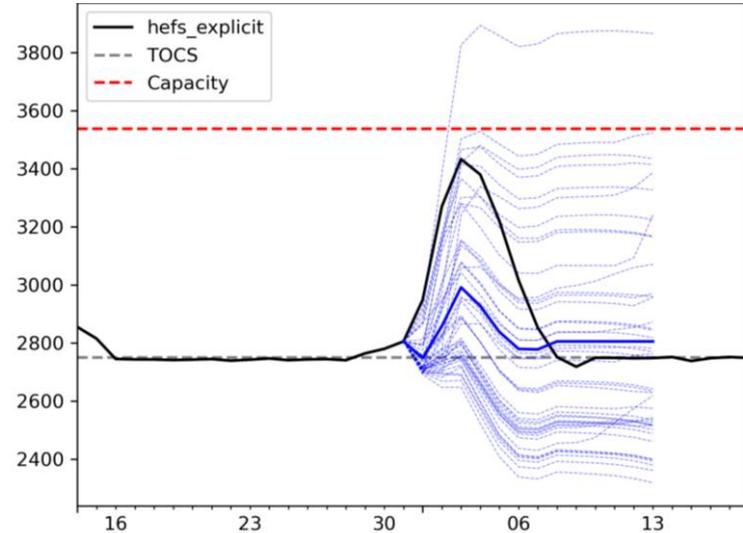

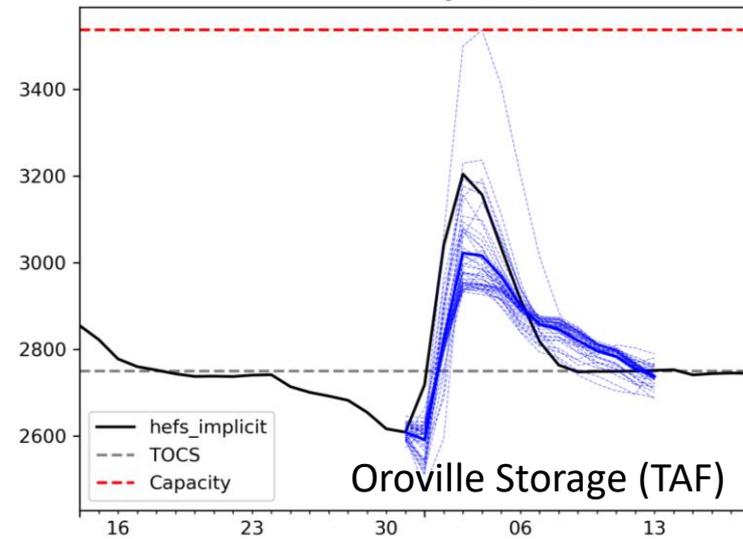

Mass balance, max/min flows, max/min storage, ramping rates, Muskingum eqns

Objective Function:

- Squared deviation from target storage (TOCS, normalized by capacity)
- Large penalty for any emergency releases exceeding u_{\max}
- Squared deficit from target demand

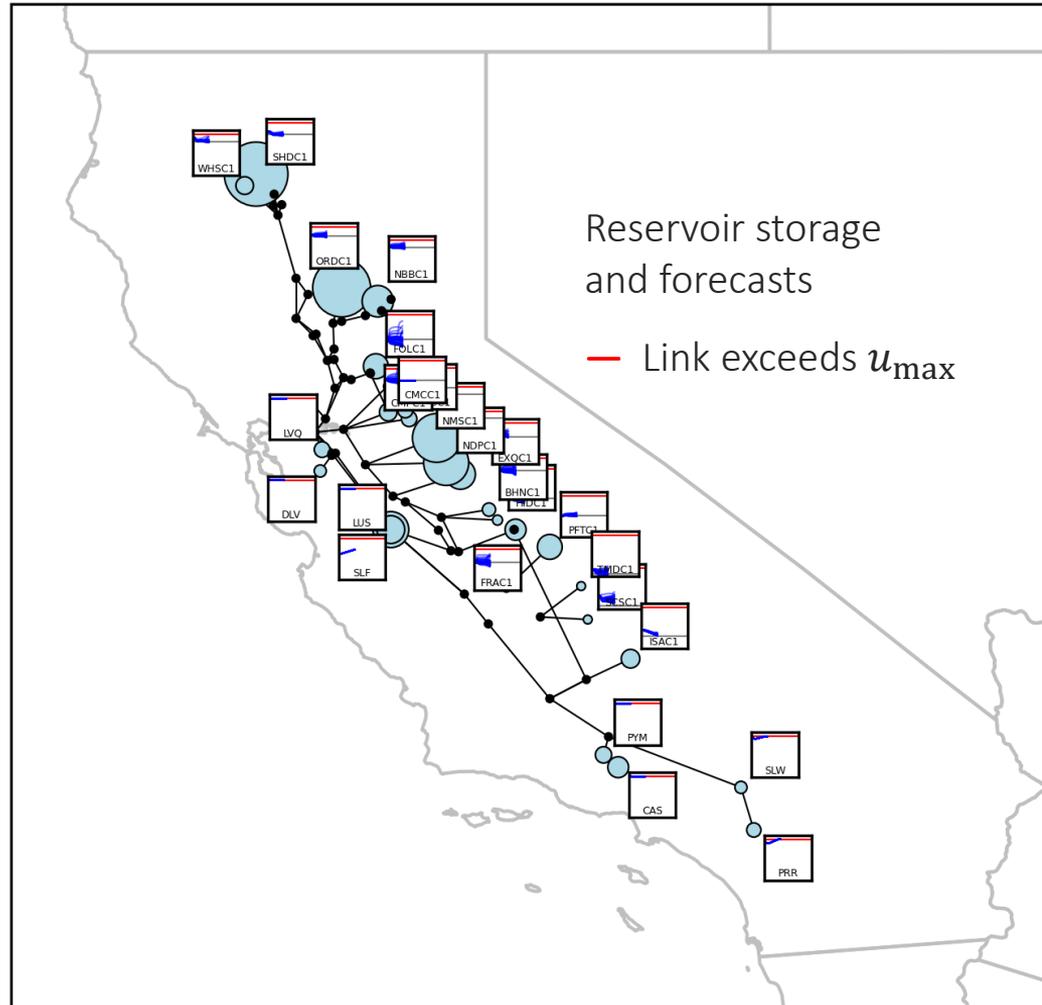

Experiment

- 1997 New Year's Flood
 - 12/10/96 – 1/20/97
- Python cvxpy with MOSEK solver
- Forecast cases: (14-day lead)
 - Baseline: No forecast
 - Perfect forecast
 - Implicit: optimize all traces separately, average the decisions
 - Explicit: optimize expected value of objective function across all traces

Routing examples

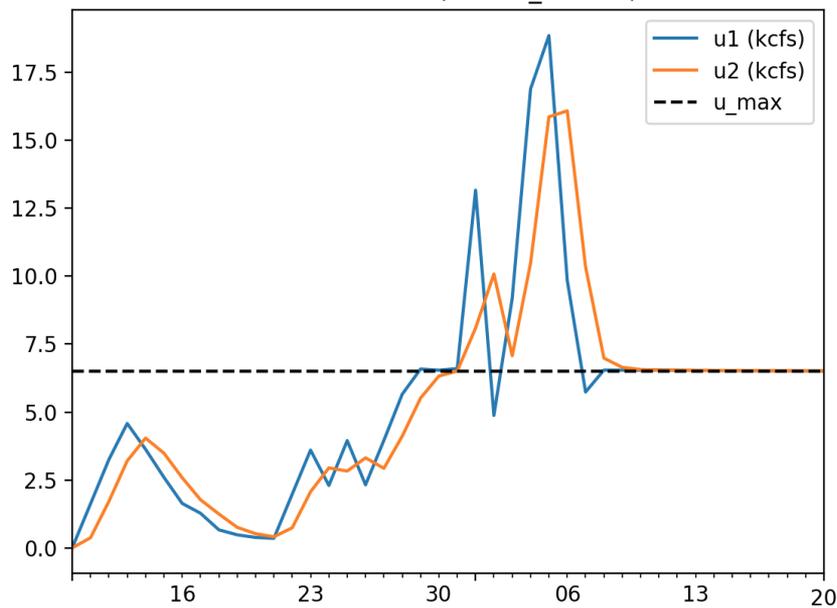

Upstream u_1 , downstream u_2

Muskingum K from DWR/GEI Travel

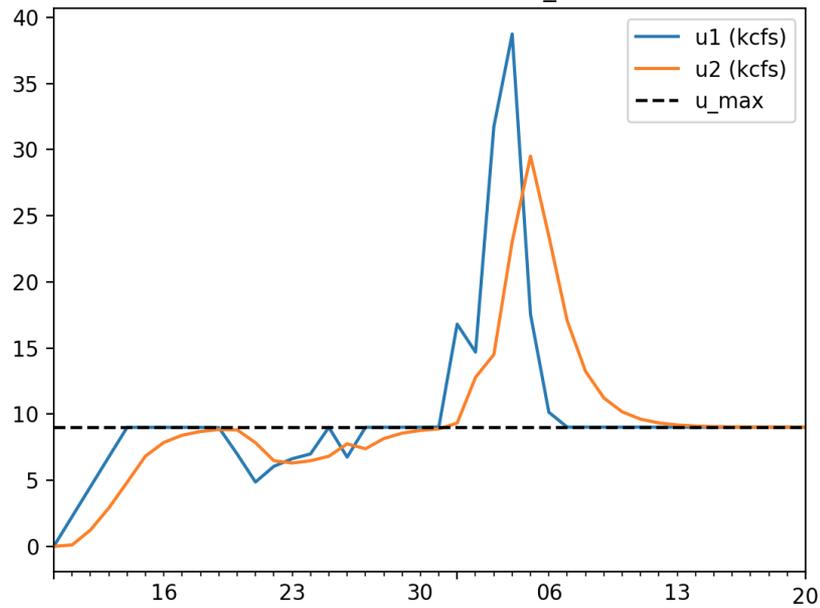

Times report (2016). Estimated $X = 0.2$.

Friant release (FRAC1_CHBC1)

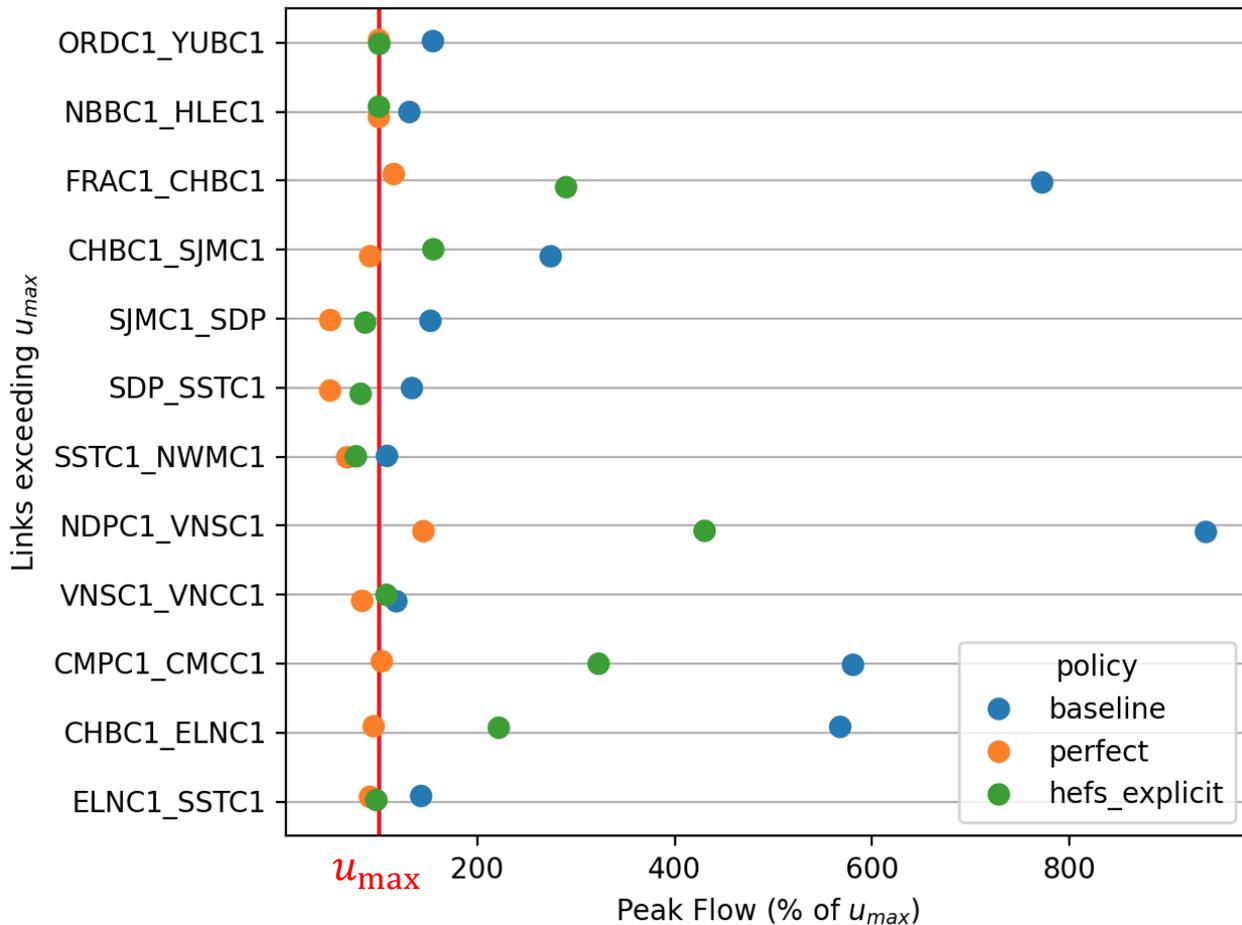

Don Pedro release (NDPC1_VNSC1)

Peak flow reduction across the network

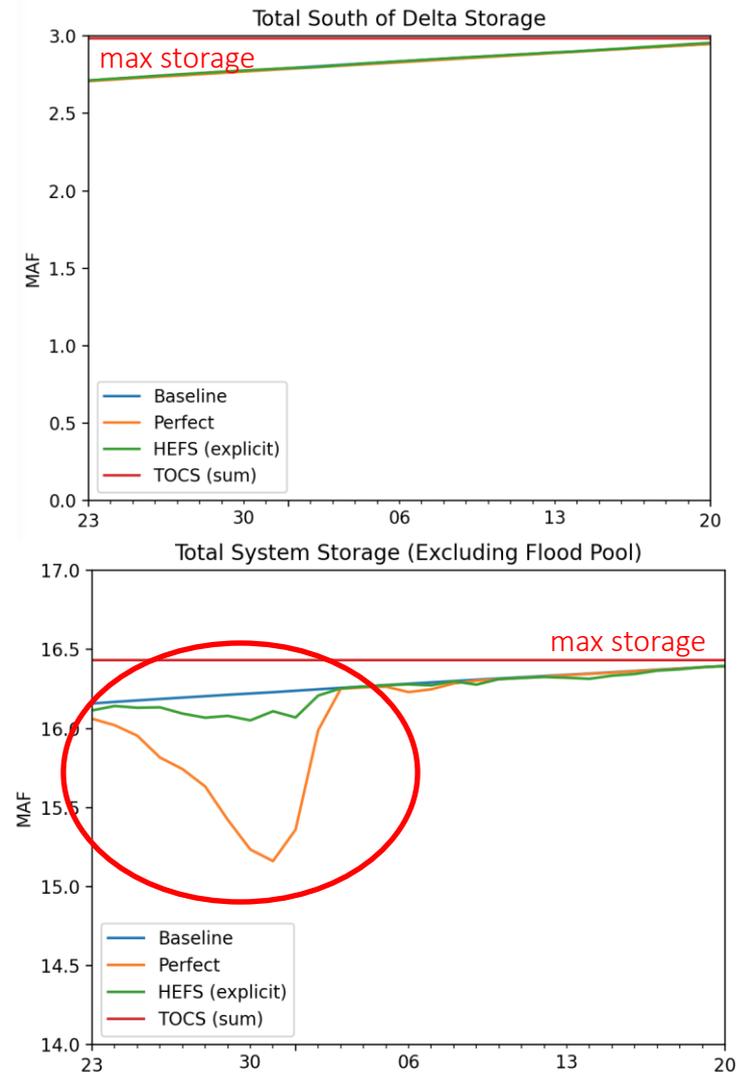

HEFS policy reduces flows above u_{max} by 50-100% compared to no-forecast baseline

Further improvement with more accurate forecasts

Water supply storage

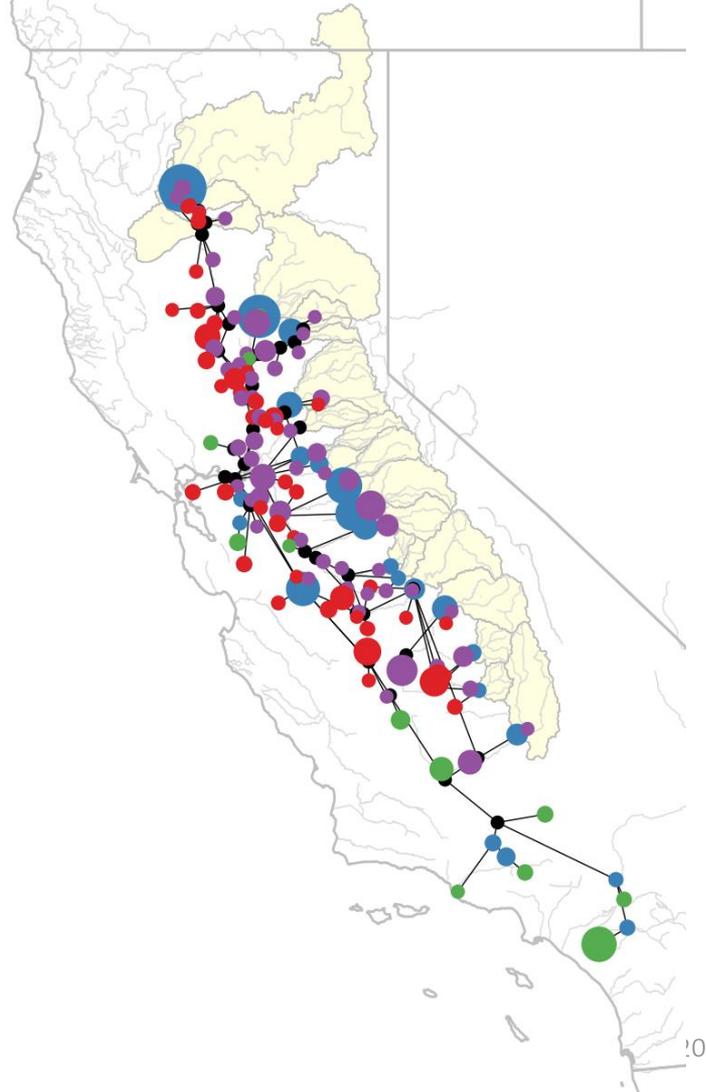

- WY 1997: not much room for improvement. The main benefit is managing flood flows.
- South of Delta storage starts almost full before the event
- In a drier year with a longer forecast horizon, there may be more storage opportunities

CA network optimization with daily ensemble forecasts

Next Steps:

- Seasonal forecasts (365-day lead)
- Full Delta constraints
- Real-time CNRFC operational forecasts
- GW banking
- Value of improved forecasts and expanded infrastructure
- Integration with DWR Flood-MAR and USACE/UCSD FIRO Phase III
- Open source & documentation (soon)

MPC (time t , N_l lead times, N_e ensemble members, N_x nodes, N_u links)

Decision Variables:

\mathbf{u}_1 = upstream flow on each link, $N_u \times N_l$

\mathbf{u}_2 = downstream flow on each link, $N_u \times N_l$

\mathbf{u}_e = emergency flow on each link (exceeds u_{\max}), $N_u \times N_l$

Parameters:

\mathbf{Q}_f = inflow forecast, $N_x \times N_l$ (for each ensemble member)

$\mathbf{M}_1, \mathbf{M}_2$ = inflow/outflow connectivity matrices, $N_x \times N_u$

\mathbf{x}_0 = initial storage, N_x

TOCS = top of conservation, $N_x \times N_l$

MPC (time t , N_l lead times, N_e ensemble members, N_x nodes, N_u links)

Mass balance: cumulative sum for lead time $k \in (1, \dots, N_l)$:

$$\Delta \mathbf{x}_k = \sum_{i=1}^k (\mathbf{Q}_f + \mathbf{M}_1 \mathbf{u}_1 + \mathbf{M}_2 \mathbf{u}_2)$$

$\mathbf{x}_f = \mathbf{x}_0 + \Delta \mathbf{x}$ = forecasted storage, $N_x \times N_l$

Objective function: minimize deviation from TOCS (normalized)
plus large penalty for emergency releases

$$\mathbf{u}_f^* = \min_{\mathbf{u}_f} \sum_r \left(\frac{\mathbf{x}_{f,r} - \mathbf{TOCS}_r}{\mathbf{K}_r} \right)^2 + w \sum_l \left(\frac{\mathbf{u}_{e,l}}{u_{\max,l}} \right)^2$$

(r = reservoirs, l = links)

Implement decisions at first timestep, $\mathbf{u}_{f,0}^*$. Move to next timestep, repeat.

Constraints:

- Max/min flows on each link: $u_f \geq u_{\min}$, $u_f \leq u_{\max} + u_e$
- Storage capacity
- Ramping rates on reservoir releases
 - estimated as 25% of u_{\max} , does not include emergency releases
- Muskingum routing equations. Routing is optional for each link, if turned off then $u_1 = u_2$. Each link has parameters K , X estimated.
